

Using technical noise to increase the signal to noise ratio in weak measurements.

Y. Kedem

Tel-Aviv University, Tel-Aviv 69978, Israel

The advantages of weak measurements, and especially measurements of imaginary weak values, for precision enhancement, are discussed. A situation is considered in which the initial state of the measurement device varies randomly on each run, and is shown to be in fact beneficial when imaginary weak values are used. The result is supported by numerical calculation and also provides an explanation for the reduction of technical noise in some recent experimental results. A connection to quantum metrology formalism is made.

In 1988 Aharonov, Albert and Vaidman (AAV) [1] discovered that the measured value of an observable can be 100 times bigger than its biggest eigenvalue, provided the measurement interaction is weak and a postselection is employed. They showed that a system which is coupled weakly to another, pre- and postselected system, described by the *two-state vector* $\langle\Phi| |\Psi\rangle$, via an observable C , is effectively coupled to the weak value of the observable [2]

$$C_w \equiv \frac{\langle\Phi|C|\Psi\rangle}{\langle\Phi|\Psi\rangle}. \quad (1)$$

The replacement of an operator with its weak value, which is a complex number [3], is known as the AAV effect and the procedure in which the weak value is measured is referred to as a weak measurement. The promise that this phenomenon holds for improving precision measurements had recently started to materialize in observation of the spin hall effect of light [4] and ultra sensitive measurement of beam deflection [5]. Other areas where the use of weak measurements was investigated include measuring small longitudinal phase shifts [6, 7], charge sensing [8], frequency measurements [9], and Kerr nonlinearities [10].

The general use of quantum effects for precision enhancements, known as quantum metrology [11], is showing significant results [12] and lately, much attention is drawn to practical issues such as the effects of an environment [13, 14], noise [15], and technical limitations [16]. According to [4, 5] the use of imaginary weak values in the measurement process, allows a reduction in technical noise. In this letter we will analyze the process of weak measurement as a method for precision measurements. Furthermore, we will consider a specific model for technical noise, affecting the preparation of the measurement device (meter), and show that in the presence of such a noise the precision is enhanced.

Consider a physical interaction:

$$H = g(t)PC, \quad (2)$$

where C is an observable on a system, P is an operator on a meter and $g(t)$ is a coupling function satisfying $\int g(t)dt = k$. Our concern is estimating the size of k , or in

some cases simply observing the interaction. A straight forward approach is to put the system in an eigenstate of C having some eigenvalue c , and the meter in a Gaussian state:

$$\Psi_M(Q) = (\Delta^2\pi)^{-1/4} e^{-\frac{Q^2}{2\Delta^2}}, \quad (3)$$

where Q is a variable conjugate to P , and Δ is its quantum uncertainty. An estimate of k can be obtained from the shift in Q due to the interaction, $\langle Q \rangle = kc$, and its precision is determined by the standard deviation $\frac{1}{\sqrt{2}}\Delta$. In the case $kc \ll \Delta$, little information is acquired from a single measurement, but by repeating the procedure N times and averaging the results, the precision is enhanced. Strictly speaking, the amount of information gathered, regarding k , is measured by the Fisher information [15], but for our purposes we can use the more intuitive concept of *signal to noise ratio* (S/N) [17], which in this case is

$$S/N = \sqrt{N} \frac{kc}{\Delta}. \quad (4)$$

Since our interest is in the regime where $kc \ll \Delta$, which is a condition for the AAV effect [18], we will, for now, assume that the AAV effect occurs and later examine its validity in more detail. Thus, we will consider the system to be initially in a state $|\Psi\rangle$ and take into account the meter results only when the system was found in a state $|\Phi\rangle$, after the interaction. The shift in Q is given by $\langle Q \rangle_\Phi = kReC_w$ [1], and

$$S/N = \sqrt{N_\Phi} \frac{kReC_w}{\Delta}, \quad (5)$$

where $N_\Phi \sim N |\langle\Phi|\Psi\rangle|^2$ is the number of times the system was found in a state $|\Phi\rangle$. In order for C_w to be larger than any eigenvalue of C , the scalar product, $\langle\Phi|\Psi\rangle$, has to be small, so we can see that we cannot improve (5) significantly, relative to (4). It is, however, a remarkable fact that by using only a small portion of our potential data, we get the same quality of information. In practice, there are many set ups where a rare postselection is beneficial, especially when there is a detection constraint, such as saturation limits or dead time.

Another option is to measure the meter in the P basis. Assuming the meter initial state is (3), which we can write in the P basis as:

$$\Psi_M(P) = (\Delta^{-2}\pi)^{-1/4} e^{-\frac{\Delta^2 P^2}{2}}, \quad (6)$$

the final shift in P is given by $\langle P \rangle_\Phi = k\Delta^{-2}\text{Im}C_w$ [3] and the standard deviation is $\frac{1}{\sqrt{2}}\Delta^{-1}$, giving us

$$S/N = \sqrt{N_\Phi} \frac{k\text{Im}C_w}{\Delta}. \quad (7)$$

Surprisingly, for $\text{Im}C_w = \text{Re}C_w$, the S/N for this case is the same as (5) and it seems measuring an imaginary weak value is ineffective. However, as we will now show, this is not the case.

In calculating the S/N (4), (5) and (7) we considered only the quantum uncertainty, sometimes called shot noise, and not any technical issues. Since the set ups used in advance experiments are highly intricate, there is an enormous range of possible technical issues and conceiving a general model for their effect is beyond the scope of this letter. Instead, we will restrict our discussion to faults in the preparation of the meter, causing its initial state to be shifted with respect to (3) or (6).

Let us start by considering a shift, Q_0 , in the Q basis only, making the initial state of the meter

$$\Psi_M(Q) = (\Delta^2\pi)^{-1/4} e^{-\frac{(Q-Q_0)^2}{2\Delta^2}}. \quad (8)$$

A measurement of Q , after an interaction (2) with a pre and postselected system $\langle \Phi | | \Psi \rangle$, will yield

$$\begin{aligned} \langle Q \rangle_\Phi &= Q_0 + k\text{Re}C_w, \\ \langle Q^2 \rangle_\Phi &= \frac{\Delta^2}{2} + (Q_0 + k\text{Re}C_w)^2. \end{aligned} \quad (9)$$

Since the shift Q_0 can be different for every run, some distribution should be used when averaging over the results. We assume an uncorrelated distribution with vanishing average $\overline{Q_0} = 0$, which can be seen as white noise. A finite average would describe a systematic error while correlations can appear, for example, if Q_0 has some time dependency which is relevant to the frequency in which the runs occur or to their total time. In order to treat such disturbances, an analysis using Allan variance [19] is needed which we will not discuss here. In [10], weak measurements was shown to be beneficial for noise with long correlation time, however, their results about its ineffectiveness for white noise was based on the measurements of real weak values.

For simplicity, we assume the distribution of the shift is Gaussian as well, i.e. the probability for the shift Q_0 to occur is

$$\text{Pr}(Q_0) = (\Delta_Q \sqrt{\pi})^{-1} e^{-\frac{Q_0^2}{\Delta_Q^2}}, \quad (10)$$

where Δ_Q is the width of the distribution of the shift. An average over Q_0 will result in

$$\begin{aligned} \overline{\langle Q \rangle_\Phi} &= k\text{Re}C_w, \\ \overline{\langle Q^2 \rangle_\Phi} &= \frac{\Delta^2}{2} + \frac{\Delta_Q^2}{2} + (k\text{Re}C_w)^2, \end{aligned} \quad (11)$$

meaning the same shift as it was for (3) but a larger standard deviation, making

$$S/N = \sqrt{N_\Phi} \frac{k\text{Re}C_w}{\sqrt{\Delta^2 + \Delta_Q^2}} \quad (12)$$

smaller than (5). Similarly we can get $S/N = \sqrt{N}kc/\sqrt{\Delta^2 + \Delta_Q^2}$ if the system is in an eigenstate of C with eigenvalue c .

By writing the meter state, in the P basis, after the interaction and postselection:

$$\Psi_M(P) = \mathcal{N}(\Delta^{-2}\pi)^{-1/4} e^{-\frac{\Delta^2 P^2}{2} + i(Q_0 - kC_w)P}, \quad (13)$$

where $\mathcal{N} = \text{Exp}[-k^2\Delta^{-2}(\text{Im}C_w)^2/2]$ is the re-normalization factor due to the postselection, one can see that a measurement of P will yield

$$\begin{aligned} \langle P \rangle_\Phi &= k\Delta^{-2}\text{Im}C_w, \\ \langle P^2 \rangle_\Phi &= \frac{\Delta^{-2}}{2} + (k\Delta^{-2}\text{Im}C_w)^2. \end{aligned} \quad (14)$$

This means that the S/N for this case,

$$S/N = \sqrt{N_\Phi} \frac{k\text{Im}C_w}{\Delta}, \quad (15)$$

is the same as (7), the S/N for the case of an ideal initial state.

This is the first result of our letter: when one has a dominant technical issue in the preparation of a variable conjugate to the interaction operator, measurements of an imaginary weak value can eliminate its effect.

Let us now consider a shift, P_0 , in the P basis, making the initial state of the meter

$$\Psi_M(P) = (\Delta^{-2}\pi)^{-1/4} e^{-\frac{\Delta^2 (P-P_0)^2}{2}}, \quad (16)$$

with probability

$$\text{Pr}(P_0) = (\Delta_P \sqrt{\pi})^{-1} e^{-\frac{P_0^2}{\Delta_P^2}}. \quad (17)$$

After an interaction (2) with a pre and postselected system $\langle \Phi | | \Psi \rangle$ the meter is in a state

$$\Psi_M(P) = \mathcal{N}_{P_0}(\Delta^{-2}\pi)^{-1/4} e^{-\frac{\Delta^2 (P-P_0)^2}{2} - ikC_w P}, \quad (18)$$

where $\mathcal{N}_{P_0}$ is the re-normalization factor due to the postselection. A final measurement of P , will yield

$$\begin{aligned} \langle P \rangle_\Phi &= P_0 + k\Delta^{-2}\text{Im}C_w, \\ \langle P^2 \rangle_\Phi &= \frac{\Delta^{-2}}{2} + (P_0 + k\Delta^{-2}\text{Im}C_w)^2. \end{aligned} \quad (19)$$

In order to calculate the average over P_0 we have to consider the probability of postselection

$$\begin{aligned} \Pr(|\Phi\rangle | P_0) &= |\langle\Phi|\Psi\rangle|^2 e^{k\text{Im}C_w(2P_0+k\text{Im}C_w\Delta^{-2})} \\ &= |\langle\Phi|\Psi\rangle|^2 \mathcal{N}_{P_0}^{-2}, \end{aligned} \quad (20)$$

which was of no importance for a shift in Q , since it did not depend on Q_0 . This means that if we prepare an ensemble of N meters, with states (16) according to the distribution (17), and then, after an interaction (2), we postselect to $|\Phi\rangle$, the postselected ensemble of meters will have a different distribution:

$$\begin{aligned} \Pr(P_0 | |\Phi\rangle) &= \frac{\Pr(P_0) \Pr(|\Phi\rangle | P_0)}{\Pr(|\Phi\rangle)} \\ &= (\Delta_P \sqrt{2\pi})^{-1} e^{-\frac{(P_0 - k\text{Im}C_w \Delta_P^2)^2}{\Delta_P^2}}. \end{aligned} \quad (21)$$

Calculating the averages using (21) we get

$$\begin{aligned} \overline{\langle P \rangle}_\Phi &= k(\Delta^{-2} + \Delta_P^2) \text{Im}C_w, \\ \overline{\langle P^2 \rangle}_\Phi &= \frac{\Delta^{-2}}{2} + \frac{\Delta_P^2}{2} + (k(\Delta^{-2} + \Delta_P^2) \text{Im}C_w)^2, \end{aligned} \quad (22)$$

yielding:

$$S/N = \sqrt{N_\Phi} k \text{Im}C_w \sqrt{\Delta^{-2} + \Delta_P^2}. \quad (23)$$

While for $\Delta_P = 0$ this S/N equals (15), for $\Delta_P > 0$ it is bigger.

This is the main result of our letter: In the regime where the AAV effect occurs, a non coherent spread in the variable appearing in the interaction improves the precision of the measurement.

In order to examine the conditions for the AAV effect, in the context of an imperfect meter preparation, we can look on the evolution (up to normalization):

$$\begin{aligned} \langle\Phi|e^{-ikPC}|\Psi\rangle &= \langle\Phi|\Psi\rangle e^{-ikC_w P} \\ &+ \langle\Phi|\Psi\rangle \sum_{n=2}^{\infty} \frac{(ikP)^n}{n!} [(C^n)_w - (C_w)^n]. \end{aligned} \quad (24)$$

The AAV effect means that the final state of the meter is determined by the first term, so we need to require that its initial state is such that the second term is negligible. When examining the expectation value of this expression, we will consider only the first term in the sum, i.e. $n = 2$, assuming the rest are smaller. An additional simplification can be done assuming $|(C^n)_w| < |C_w|^n$ for $n > 1$, which is the case, in general, for a weak value that is larger than any eigenvalue, limiting our concern to verifying the condition: $|kC_w|^2 \langle P^2 \rangle \ll 1$. For the state (8), it amounts to $|kC_w|^2 \Delta^{-2} \ll 1$, implying that there is no dependency on the distribution of Q_0 and also that for a purely real (imaginary) weak value, the S/N (5) (7) have to be small for $N_\Phi = 1$. Thus, a small S/N per measurement is a necessary condition for the AAV effect. For the state (16), with a distribution (17), we have

$$|kC_w|^2 (\Delta^{-2} + \Delta_P^2) \ll 1, \quad (25)$$

Figure 1. The expected results of a final measurement of P , based on equation (26): The probability distribution for $w = 8$ (TOP) and the S/N per measurement (Bottom). The center of the distribution is shifted in proportion to Δ_T , however, when $wk\Delta_T \sim 1$ part of the distribution start appearing on the wrong side. For small Δ_T , the S/N is increasing linearly, in agreement with (23). The maximum is around $wk\Delta_T \sim 1$. From (25) it is clear that for larger values of Δ_T the AAV effect is not valid, and thus the S/N is getting smaller, as expected for standard measurements. In an experiment aimed at measuring a tiny effect, such as [4] and [5], the interaction strength, k , would be very small making $k\Delta_T \ll 1$ the relevant regime and only with the factor $\sqrt{N_\Phi} \sim \sqrt{N}/w$, due to N repetitions, can the S/N be larger than unity.

implying that in order to make the S/N (23) large, for any value of Δ_P , one has to perform many measurements.

We support our results with a numerical calculation of a simple example, in which the pre and postselected system is a two level system (qubit) described by $(4 + 4w^2)^{-1/2} (|\uparrow\rangle + |\downarrow\rangle) ((1 + iw)|\uparrow\rangle + (1 - iw)|\downarrow\rangle)$, where $|\uparrow\rangle$ ($|\downarrow\rangle$) is an eigenstate of C with eigenvalue 1 (-1). The weak value is given by $C_w = iw$, but our calculation is not based on the AAV effect. For an initial state of the meter that is described by (16) and (17), we find that the distribution of a final measurement of P is given by

$$\rho(P) = \frac{2e^{k^2\Delta_T^2 - \frac{P^2}{\Delta_T^2}} |\cos(kP) + w \sin(kP)|^2}{(1 - w^2 + (1 + w^2)e^{k^2\Delta_T^2}) \sqrt{\pi}\Delta_T}, \quad (26)$$

where $\Delta_T = \sqrt{\Delta^{-2} + \Delta_P^2}$. This distribution and the S/N per measurement, $\overline{P}/\sqrt{\overline{P^2} - \overline{P}^2}$, for it, are plotted in Fig. 1.

In order to put our results in an experimental context, we analyze two experiments, [4] and [5], where weak

measurements were used to detect tiny modifications in a paraxial light beam. In [4] the beam was displaced by the spin hall effect of light, creating a polarization dependent change in its transverse spatial distribution. They considered an effective Hamiltonian of the form of (2), with C being a polarization variable, P the transverse momentum and k was a small coefficient that needed to be estimated. Polarizers were used for the pre and post-selection, making C_w purely imaginary, and a position sensor was located in a distance such that the center of the spatial distribution was determined by the transverse momentum immediately after the interaction.

In [5], a Sagnac interferometer was used where the angle of one of the mirrors changed the beams direction, depending on which path it took in the interferometer. The analogue interaction of the type (2) is having C as the which-path variable, P as transverse position and k as the angle of the mirror times the light wave number. The interferometer was set up to make the weak value purely imaginary, and lenses were used to make the transverse position of the beam at detection proportional to the transverse position immediately after the interaction, up to a geometrical optical factor.

Thus, even though the interactions were of different nature, both results should agree with (22). The manifestation of $\Delta^{-2} + \Delta_p^2$ in an experiment would be the square of the width of the final measurement, and indeed, in both experiments the final result was proportional to this quantity. It was also mentioned in [5], [4] and [6] that this method was especially beneficial for technical noise. Distinguishing between the coherent width Δ^{-1} , and the one caused by technical issues, Δ_p , can be rather difficult, but it is unnecessary in our formalism.

Unlike the common practice in quantum metrology [11, 15], our results do not require the meters to be entangled. The correlations created by the postselection can be viewed as classical ones and thus the precision scales as $\sqrt{N}$. The way this method improves the Cramér-Rao bound is simply by increasing ΔH , a task that can be done in a non-coherent way, and thus might be much simpler, experimentally, than the creation of entanglement.

An important aspect of our result is the effect of the meter on the system, usually called backaction. One can also consider the measurement interaction (2) with reversed roles, i.e. regard P as acting on a system and C on a meter. k could be measured, for example, by putting the meter in an initial state $|\Psi\rangle$, the system in a state $P = P_0$ and measuring the probability to find it in a state $|\Phi\rangle$: $|\langle\Phi|e^{-ikP_0C}|\Psi\rangle|^2 = |\langle\Phi|\Psi\rangle|^2 (1 + 2k\text{Im}C_w P_0) + O(kP_0)^2$. The binomial distribution gives an S/N of

$$S/N = 2k\text{Im}C_w P_0 \sqrt{\frac{N |\langle\Phi|\Psi\rangle|^2}{(1 - |\langle\Phi|\Psi\rangle|^2)}}, \quad (27)$$

which is comparable to (23) with the replacement $P_0 \leftrightarrow$

$\sqrt{\Delta^{-2} + \Delta_p^2}$. This highlights some of the differences in the experimental challenges each method presents, with regard to the preparation and measurement of P . Naturally, experimental issues concerning $\langle\Phi|\Psi\rangle$ can also have different effects depending on the chosen method.

The AAV effect is valid for qubit meter as well [20] and, when it is used, technical issues in its preparation can naturally lead to reduced S/N . Since the uncertainty of any qubit variable is bounded, measurements of imaginary weak values cannot yield an improved S/N relative to other methods, according to our results. However, such measurements can yield the same S/N regardless if the meter uncertainty is coherent or not.

We have shown that in the scenario of measurement of imaginary weak values, a shortcoming in the ability to prepare the meter in an exact known state, does not diminish the precision and the result of some flawed preparation can in fact increase the precision. This phenomenon explains some remarkable recent results where technical noise was overcome and it has the potential to improve many quantum metrology schemes in a novel way.
